Abstract

Background: Schistosomes are trematode parasites of the Phylum Platyhelminthes. They are considered the most important of the human helminth parasites in terms of morbidity and mortality. Draft genome sequences are now available for *Schistosoma mansoni* and *Schistosoma japonicum*. Non-coding RNA (ncRNA) plays a crucial role in gene expression regulation, cellular function and defense, homeostasis, and pathogenesis. The genome-wide annotation of ncRNAs is a non-trivial task unless well-annotated genomes of closely related species are already available.

Results: A homology search for structured ncRNA in the genome of *S. mansoni* resulted in 23 types of RNAs with conserved primary and secondary structure. Among these, we identified rRNA, snRNA, SL RNA, SRP, tRNAs and RNase P, and also possibly MRP and 7SK RNAs. In addition, we confirmed five miRNAs that have recently been reported in *S. japonicum* and found two additional homologs of known miRNAs. The tRNA complement of *S. mansoni* is comparable to that of the free-living planarian *Schmidtea mediterranea*, although for some amino acids differences of more than a factor of two are observed: Leu, Ser, and His are overrepresented, while Cys, Meth, and Ile are underrepresented in *S. mansoni*. Several ncRNAs that are expected to exist in the *S. mansoni* genome were not found, among them the telomerase RNA, vault RNAs, and Y RNAs.

Conclusions: The ncRNA sequences and structures presented here represent the most complete dataset of ncRNA from any lophotrochozoan reported so far. It provides a key addition to our understanding of the genomes of schistosomes and indeed eukaryotic genomes at large.

Background

Non-coding RNA (ncRNA) plays a crucial role in gene expression regulation, cellular function and defense, and disease [1]. In contrast to protein-coding mRNAs, ncRNAs do not form a homogeneous class. The best-characterized subclasses form stable basepairing patters (secondary structures) that are crucial for the their function. This group includes the well-known tRNAs, catalytically active RNAs such as rRNA, snRNAs, RNAse P RNA, and other ribozymes, and regulatory RNAs such as microRNAs and spliceosomal RNAs that direct protein complexes to specific RNA targets.

Most non-vertebrate genome projects have put little emphasis on a comprehensive annotation of ncRNAs. Indeed, most non-coding RNAs, with the notable exception of tRNAs and rRNAs, are difficult or impossible to detect with **blast**. Hence their annotation is not part of generic genome annotation pipelines. Dedicated computational searches for particular ncRNAs, for example, RNAse P and MRP [2,3], 7SK RNAs [4,5], or telomerase RNA [6,7], are veritable research projects in their own right. Despite best efforts, large territory remains uncharted across the animal phylogeny.

The main difficulty with ncRNA annotation is poor sequence conservation and indel patterns that often correspond to large additional "expansion domains". In many cases, the secondary structure is much better conserved than the primary sequence, providing a means of confirming candidate ncRNAs even in cases where sequence conservation is confined to a few characteristic motifs. Secondary structure conservation can also be utilized to detect homologs of some ncRNAs based on characteristic combinations of sequence and structure motifs using special software tools designed for this purpose.

In [8] we described a protocol for a more detailed homology-based ncRNA annotation than what can be achieved with currently available automatic pipelines. Here we apply this scheme to the genome of S. mansoni.

Schistosomes belong in an early-diverging group within the Digenea, but are clearly themselves highly derived [9–11]. The flatworms are a long-branch group, suggesting rapid mutation rates (see [12]).

Schistosome genomes are comparatively large, estimated at about 300 megabase pairs for the haploid genome of *Schistosoma mansoni* [13]. The other major schistosome species parasitizing humans probably have a genome of similar size, based on the similarity in appearance of their karyotypes [14]. These large sizes may be characteristic of platyhelminth genomes in general: the genome of *Schmidtea mediterranea*, the only other sequenced platyhelminth genome, is even larger, with the current genome sequencing project reporting a size of ~ 480 megabase pairs [15]¹.

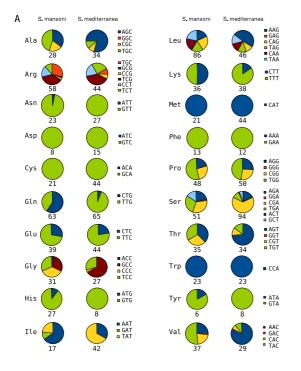

The protein-coding portion of the Schistosoma genomes have received much attention in recent Published work includes transcriptome years. databases for both S. japonicum [16] and S. mansoni [17], characterization of promoters [18, 19], and physical mapping and annotation of protein-coding genes from both the S. mansoni and S. japonicum genome projects [20]. Recently, a systematic annotation of protein-coding genes in S. japonicum was reported [21]. In contrast to other, better-understood, parasites such as *Plasmodium* [22], however, not much is known about the non-coding RNA complement of schistosomes. Only the spliced leader RNA (SL RNA) of S. mansoni [23], the hammerhead ribozymes encoded by the SINE-like retrotransposons Sm- α and Sj- α [24, 25], and secondary structure elements in the LTR retrotransposon *Boudicca* [26] have received closer attention. Ribosomal RNA sequences have been available mostly for phylogenetic purposes [27], and tRNAs have been studied to a limited degree [28].

In this contribution we give a comprehensive overview of the evolutionary conserved non-coding RNAs in the S. mansoni genome. We discuss representatives of 23 types of ncRNAs that were detected based on both sequence and secondary structure homology.

Results & Discussion

Structure and homology-based searches of the *S.* mansoni genome revealed ncRNAs from 23 different RNA categories. Table 2 lists these functional ncRNA category, the number of predicted genes in each category, and references associated with each RNA type. Supplementary fasta files containing the ncRNA genes, bed files with the genome annotation, and stockholm-format alignment files can be accessed at http://www.bioinf.uni-leipzig.de/ Publications/SUPPLEMENTS/08-014.

Transfer RNAs

Candidate tRNAs were predicted with tRNAscan-SE in the genomes of both *S. mansoni* and *S. mediterranea* (a free-living platyhelminth, used for comparison). After removal of transposable element sequences (see below), tRNAscan predicted a total of 663 tRNAs for *S. mansoni* and 728 for *S. mediterranea*. These included tRNAs encoding the standard 20 amino acids of the traditional genetic code, selenocysteine encoding tRNAs (tRNAsec) [29] and possible suppressor tRNAs [30] in both genomes. The tRNAsec from schistosomes has been characterized, and is similar in size and structure to tRNAsec from other eukaryotes [31].

The tRNA complements of the two platyhelminth genomes are compared in detail in Figure 1. While most amino acids were represented in approximately equal numbers in the two species, there are several notable deviations. *S. mansoni* contains many more leucine (86 vs. 46) and histidine (27 vs. 8) tRNAs, while serine (51 vs. 94), cysteine (21 vs. 44), methionine (21 vs. 44), and isoleucine (17 vs. 42) are underrepresented. In addition, there are several substantial differences in codon usage. In most cases, *S. mansoni* has a more diverse repertoire of tRNAs: tRNA-Asn-ATT, tRNA-Arg-CGC, tRNA- His-ATG, tRNA-Ile-GAT, tRNA-Pro-GGG, tRNA-Tyr-ATA, tRNA-Val-GAC are missing in *Schmidtea*. Only tRNA-Ser-ACT is present in *Schmidtea* but absent in *Schistosoma*.

It has recently been shown that changes in codon usage, even while coding the same protein sequences, can severely attenuate the virulence of viral pathogens [32] by "de-optimizing" translational efficiency. This observation leads us to speculate that the greater diversity of the tRNA repertoire could be related to the selection pressures of the parasitic lifestyle of *S. mansoni*. It would be interesting therefore to investigate in detail the possibility of differences in codon usage of proteins highly expressed in the different stages of *S. mansoni*'s life cycle.

The most striking result of the tRNAscan-SE analysis was the initial finding of 1,135 glutamine tRNAs (Gln-tRNAs) in *S. mansoni*, in contrast to 65 Gln-tRNAs in *S. mediterranea*. Nearly all of these (1,098) were tRNA-Gln-TTG. In addition, an extreme number of 1,824 tRNA-pseudogenes in *S. mansoni* (vs. 19 in *S. mediterranea*) were predicted. Of these, 1,270 were homologous to tRNA-Gln-TTG. These two groups of tRNA-Gln-TTG-derived genes (those predicted to be pseudogenes and those predicted to be functional tRNAs) totaled 2,368. These high numbers suggest a tRNA-derived mobile genetic element. We therefore ran the 2,368 tRNA-Gln-TTG genes through the RepeatMasker program [33]. Almost all of them (2,342) were classified as SINE elements. Further **blast** analysis revealed that these elements are similar to members of the Sm- α family of *S. mansoni* SINE elements [34]. Removal of these SINE-like elements yielded a total of 26 predicted glutamine-encoding tRNAs in *S. mansoni*.

Homology-based analysis yielded similar, though somewhat less sensitive, results to those of tRNAscan-SE. A blast search with Rfam's tRNA consensus yielded 617 predicted tRNAs compared to the 663 predictions made by tRNAscan.

Ribosomal RNAs

As usual in eukaryotes, the 18S, 5.8S, and 28S genes are produced by RNA polymerase I from a tandemly repeated polycistronic transcript, the ribosomal RNA operon. The S. mansoni genome contains about 90-100 copies [35, 36] which are nearly identical at sequence level, because they are subject to concerted evolution [37]. The repetitive structure of the rRNA operons causes substantial problems for genome assembly software [38]. In order to obtain a conservative estimate of the copy number, we retained only partial operon sequences that contained at least two of the three adjacent rRNA genes. We found 48 loci containing parts of 18S, 5.8S, and 28S genes, 32 loci covering 18S and 5.8S rRNA, and 57 loci covering 5.8S and 28S rRNAs (Supplemental Figure S1, S2). Adding the copy numbers, we have not fewer than 80 copies (based on linked 18S rRNAs) and no more than 137 copies (based on linked 5.8S rRNA). The latter is probably an overestimate due to the possibility that the 5.8S rRNA may be contained in two scaffolds. The copy number of rRNA operons is thus consistent with the estimate of 90-100 from hybridization analysis [35].

The 5S rRNA is a polymerase III transcript that has not been studied in *S. mansoni* so far. We find 21 copies of the 118nt long 5S rRNA. Four of these copies are located within a 3000nt cluster on *Scaf*fold010519.

Spliceosomal RNAs and Spliced Leader RNA

Spliceosomes, the molecular machines responsible for most splicing reactions in eukaryotic cells, are ribonucleoprotein complexes similar to ribosomes [39]. The major spliceosome, which cleaves GT-AG introns, includes the five snRNAs U1, U2, U4, U5, and U6. In the *S. mansoni* genome, all of them are multicopy genes. By homology search we found 34 U1, 15 U2, 19 U4, 9 U5, and 55 U6 sequences in the genome assembly. Interpreting all sequences that are identical in short flanking regions as the same, we would retain only 3 U1, 3 U2, 1 U4, 2 U5, and 9 U6 genes [40]. The true copy number in the *S. mansoni* genome is most likely somewhere between these upper and lower bounds. Secondary structures for these are similar to those of typical snRNAs, Fig. 2.

A second, much less frequent, minor spliceosome is responsible for the processing of atypical AT–AC introns. It shares only the U5 snRNA with the major spliceosome. The other four RNA components are replaced by variants called U11, U12, U4atac, and U6atac [41]. The minor-spliceosomal snRNAs are typically much less conserved than the RNA components of the major spliceosome [40]. It was not surprising, therefore, that these RNAs were detectable only by means of GotohScan [8] but not with the much less sensitive blast searches. Although U4atac and U6atac are quite diverged compared to known homologs, they can be recognized based on both secondary structure and conserved sequence motifs. Furthermore, the U4atac and U6atac sequences can interact to form the functionally necessary duplex structure shown in Fig. 2.

An analysis of promoter sequences showed that the putative snRNA promoter motifs in *S. mansoni* are highly derived. Only one of the two U12 genes exhibits a clearly visible snRNA-like promoter organization.

The Spliced Leader (SL) RNA is one of the very few previously characterized ncRNAs from S. mansoni [23]. The 90nt SL RNA, which was found in a 595nt tandemly repeated fragment (accession number M34074), contains the 36nt leader sequence at its 5' end which is transferred in the transsplicing reaction to the 5' termini of mature mRNAs. Using blastn, we identified 54 SL RNA genes. These candidates, along with 100nt flanking sequence, were aligned using ClustalX, revealing 6 sequences with aberrant flanking regions, which we suspect to be pseudogenic. The remaining sequences are 43 identical copies and 5 distinct sequence variants. A secondary structure analysis corroborates the model of [23], according to which the S. mansoni SL RNA has only two loops, with an unpaired Sm binding site (Supplemental Figure S3). This coincides with the

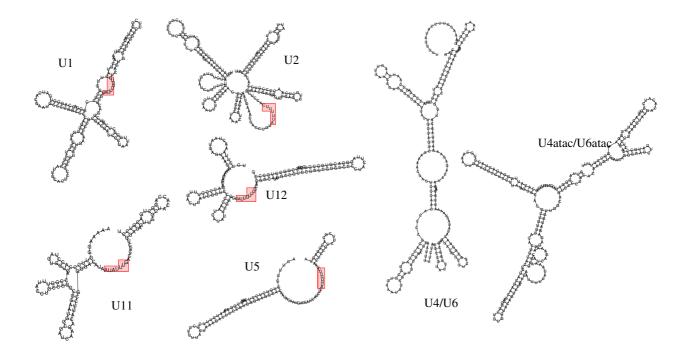

Figure 2: Secondary structures of the 9 snRNAs and the interaction complexes of U4/U6 and U4atac/U6atac, respectively.

SL RNA structure of Rotifera [42], but is in contrast to the SL RNAs in most other groups of eukaryotes, which exhibit single or triple stem-loop structures [43]. A blast-search against *S. mansoni* EST data confirms that the 5' part of the SL is indeed transpliced to mRNAs.

SRP RNA and Ribonuclease P RNA

Signal recognition particle (SRP) RNA, also known as 7SL RNA, is part of the signal recognition particle, a ribonucleoprotein that directs packaged proteins to their appropriate locations in the endoplasmic reticulum. Although one of the protein subunits of this ribonucleoprotein was cloned in 1995 [44], little is known about the other subunits or the RNA component in *S. mansoni*. We found eight probable candidates for the SRP RNA, with one almost canonical sequence (Supplemental Figure S4), and four possible candidates with point mutations which may influence their function.

The RNA component of Ribonuclease P (RNase P) is the catalytically active part of this enzyme that is required for the processing of tRNA precursors [45,46]. We found one classic RNase P RNA in

the *S. mansoni* genome using both GotohScan and RNAbob with the eukaryotic ("nuclear") Rfam consensus sequence for RNase P as search sequence.

MicroRNAs

MicroRNAs are small RNAs that are processed from hairpin-like precursors, see e.g. [47]. They are involved in post-transcriptional regulation of mRNA molecules. So far, no microRNAs have been verified experimentally in S. mansoni. The presence of four protein-coding genes encoding crucial components of the microRNA processing machinery (Dicer, Argonaut, Drosha, and Pasha/DGCR8) [48,49], and the presence of Argonaut-like genes in both S. japonica [50] and S. mansoni (detected by tblastn in EST data, see Supplemental Material), strongly suggests that schistosomes have a functional microRNA system. Indeed, most recently five miRNAs were found by direct cloning for S. *japonicum* that are also conserved in S. mansoni [51]: let-7, mir-71, bantam, mir-125, and a single schistosome-specific microRNA. The precursor sequences, however, are quite diverged from the consensus of the homologous genes in Bilateria.

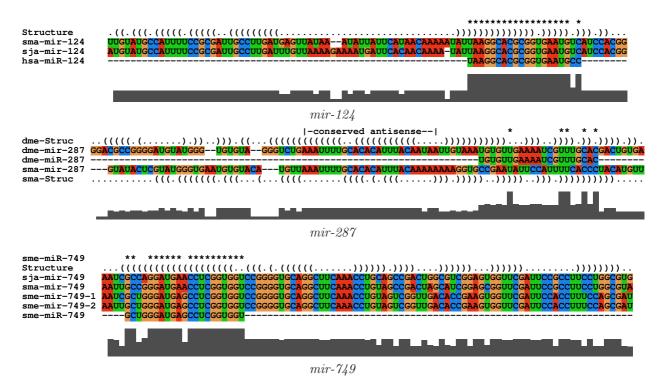

Figure 3: Multiple sequence alignments of the *pre*-miRNAs that were computationally found in *S. mansoni*. For *mir-124* and *mir-749* the sequences share a common consensus structure. The uncertain *mir-287* candidate, that clusters together with *mir-124* in the insect genomes, also shows a single stem-loop structure which, however is different from that of insects. Here the sequence is only conserved at the antisense region of the annotated mature miRNA.

Using bioinformatics (see methods) we were able to find only one further miRNA candidate in *S. mansoni, mir-124*, that is also conserved in *S. japonicum*. In insects this miRNA is clustered with *mir-287*. The distance of both miRNAs is approximately 8kb in Drosophilids. We found an uncertain *mir-287* candiate in *S. mansoni*, however, on a different scaffold than *mir-124*. Although this sequence nicely folds into a single stem-loop structure, it is conserved only antisense to the annotated mature sequence in insects (see, Figure 3). This *S. mansoni mir-287* candidate seems not to be conserved in *S. japonicum*.

In [52], 71 microRNAs are described for the distantly related trematode *Schmidtea mediterranea*, and additional ones are announced in a recent study focussing on piRNAs [53]. The overwhelming majority, 54, were reported to be members of 29 widely conserved metazoan microRNA families, although in some cases even the mature miRNA sequence is quite diverged. Therefore, we regard several family assignments as tentative at best. Of those 29 miRNAs, we found mir-124 only. Though, the schistosome sequences are more related to the other bilaterian mir-124 homologs than to those of *S. mediterranea*. Out of the remaining 54 miRNAs that were annotated in *S. mediterranea* we found that mir-749 is also conserved in the two schistosome species. Here, the sequences show a common consensus sequence and secondary structure in their precursors (see Figure 3).

The small number of recognizable microRNAs in schistosomes is in strong constrast to the extensive microRNA complement in *S. mediterranea*, indicating massive loss of microRNAs relative to the planarian ancestor. This may be a consequence of the parasitic lifestyle of the schistosomes.

Small Nucleolar RNAs

Small nucleolar RNAs play essential roles in the processing and modification of rRNAs in the nucleolus

Table 1: Conservation and target prediction of snoRNA candidates. Only ribosomal RNAs were searched for putative target sites.

snoReport	Box C/D (snoscan)			Box H/ACA (RNAsnoop)		
targets	≥ 2	1	0	≥ 2	1	0
predicted in S. mansoni	926	110	613	284	495	177
conserved in S. japonicum	200	27	83	149	203	62

[54,55]. Both major classes, the box H/ACA and the box C/D snoRNAs are relatively poorly conserved at the sequence level and hence are difficult to detect in genomic sequences. This has also been observed in a recent ncRNA annotation project of the *Trichoplax adhaerens* genome [8]. The best-conserved snoRNA is the atypical U3 snoRNA, which is essential for processing of the 18S rRNA transcript into mature 18S rRNA [56]. In the current assembly of the *S. mansoni* genome we find six U3 loci, but they are also identical in the flanking sequences, suggesting that in fact there is only a single U3 gene. No unambiguous homologue was detected for any of the other known snoRNAs.

A *de novo* search for snoRNAs (see methods for details) resulted in 2610 promising candidates (1654 box C/D and 956 box H/ACA), listed in the Electronic Supplement. All these predictions exhibit highly conserved sequence boxes as well as the typical secondary features of box C/D and box H/ACA snoRNAs, respectively.

A comparison of the predicted snoRNAs with the entries in the Rfam [57] and Noncode [58] databases returned only 47 hits that match to several other RNAs like tRNAs, parts of the rRNA operon, snR-NAs, mRNAlike genes and a few of our candidates map to the hammerhead ribozyme. These sequences are likely false positives and have been removed from the candidate list. The number of predicted candidates is much larger than the number of snoRNAs reported in other organisms; for instance [55] lists 456 for the human genome. Although we most likely do not yet know the full snoRNA complement of eukaryotic genomes, we have to expect that a large fraction of prediction will turn out to be false positives.

We therefore analysed the conservation of the candidates in *S. japonicum* and focussed on the snoRNA candidates with targets in the 18S, 28S and/or 5.8S ribosomal RNA. While targets are predicted for more than half of the candidates, see Ta-

ble 1, the numbers are drastically reduced when conservation of the candidates in *S. japonicum* is required. Note, furthermore, that the fraction of conserved candidates is strongly enriched among those with ribosomal RNA targets, indicating that these sets are likely to contain a sizeable fraction of true positives. This filtering step leaves us with 227 box C/D and 352 box H/ACA snoRNA candidates. While still high, these numbers fall into the expected range for a metazaon snoRNA complement.

We remark, finally, that five of the snoRNA candidates (3 box C/D and 2 box H/ACA) are also conserved *Schmidtea mediterranea*.

Other RNA Motifs

Two examples of relatively well-known schistosome non-coding RNA are the hammerhead ribozyme motifs within the Sm- α and Sj- α SINE-like elements [24, 25]. A **blastn** search of the hammerhead ribozyme motif from the **Rfam** database resulted in 24,447 candidates. While high, this number is not surprising considering the generally high copy number of SINE elements; previously, the copy number for Sm- α elements in the *S. mansoni* genome was estimated to exceed 10,000 [24]. The potassium channel RNA editing signal is another structured RNA element that was decribed previously [59]. We found three copies of the gene for this signal in the *S. mansoni* genome assembly.

Uncertain Candidates

Both the MRP RNA [2,3,61] and the 7SK RNA [4,5] have highly variable, rapidly evolving sequences that make them difficult or impossible to detect in invertebrate genomes. It is not surprisingly, therefore, we were not able to identify unambiguous homologs in *Schistosoma mansoni*.

MRP RNA has multiple functions, among them mitochondrial RNA processing and nucleolar pre-

rRNA processing. The *S. mansoni* MRP candidate fits the general secondary structure model of metazoan MRP RNAs [2, 3, 61] and analysis with **RNAduplex** shows that the candidate contains a pseudoknot which exhibited striking sequence identity with known MRPs. On the other hand, stems 1 and 12 were divergent compared with known MRPs, and stem 19 also failed to display clear similarity to those of known MRPs. We therefore consider this sequence only tentative.

7SK RNA is a general transcriptional regulator, repressing transcript elongation through inhibition of transcription elongation factor PTEFb and also suppresses the deaminase activity of APOBEC3C [62]. The *S. mansoni* 7SK candidate has a 5' stem similar to that described in other invertebrates [5], and parts of the middle of the sequence are also recognizable. However, the 3' stem (which was followed by a poly-T terminator) was not conserved. In addition, a large sequence deletion was evident.

Unexpectedly, no candidate sequence was found for a telomerase RNA. *S. mansoni* almost certainly has a canonical telomerase holoenzyme, since it encodes telomerase proteins (Smp_066300 and Smp_066290) and has the same telomeric repeat sequences as many other metazoan animals [63]. Telomerase RNAs are notoriously difficult to find, as they are highly divergent among different species, varying in both size and sequence composition [64].

Conclusions

We have described here a detailed annotation of "housekeeping" ncRNAs in the genome of the parasitic planarian *Schistosoma mansoni*. Limited to the best conserved structured RNAs, our work nevertheless uncovered important genomic features such as the existence of a schistosome-specific SINE family derived from tRNA-Gln-TTG. Our data furthermore establish the presence of a minor spliceosome in schistosomes and confirms spliced-leader transsplicing.

Platyhelminths are known to be a fast-evolving phylum [65]. It is not surprising therefore that in particular the small ncRNAs are hard or impossible to detect by simple homology search tools such as blastn. Even specialized tools have been successfull in identifying only the better conserved genes such as tRNA, microRNAs, RNAse P RNA, SRP RNA. Notoriously poorly conserved families, such as snoRNAs, mostly escaped detection.

The description of several novel and in many case quite derived ncRNAs contributes significantly to the understanding of the evolution of these RNA families. The schistosome ncRNA sequences, furthermore, are an important input to subsequent homology search projects, since they allow the construction of improved descriptors for sequence/structure-based search algorithms. Last but not least, the ncRNA annotation track is an important contribution to the genome-wide annotation dataset. It not only completes the protein-based annotation but also helps to identify annotation errors, e.g. cases where putative proteins are annotated that overlap rRNA operons or other ncRNAs.

Methods

tRNA Annotation

We used tRNAscan-SE [66] with default parameters to annotate putative tRNA genes. As additional confirmation, the genome sequence was searched using tRNA consensus sequences from the Rfam database [57]. In order to obtain suitable data for comparison, the genome of the free-living platyhelminth *Schmidtea mediterranea* [15] was searched alongside that of *S. mansoni*.

microRNA Annotation

We followed the general protocol outlined in [8] to identify miRNA precursors, using all metazoan miRNAs listed in miRBase [67] [Release 11.0, http: //microrna.sanger.ac.uk/sequences/]. The initial search was conducted by blastn with E < 0.01with the mature and mature^{*} miRNAs as query sequences. The resulting candidates were then extended to the length of the precursor sequence of the search query and aligned to the precursors using ClustalW [68]. Secondary structures were predicted using RNAfold [69] for single sequences and **RNAalifold** [70] for alignments. Candidates that did not fold into miRNA-like hairpin structures were discarded. The remaining sequences were then examined by eye to see if the mature miRNA was well-positioned in the stem portion of each putative precursor sequence. In addition, we used the final candidates to search the S. *japonicum* and S. *mediterranea* genomes to examine whether these sequences are conserved in Schistosoma and/or Platy-helminthes.

snoRNA Annotation

We compared all the known human and yeast snoR-NAs that are annotated in the snoRNAbase [71] to the S. mansoni genome using NCBI-blast [72] and Gotohscan [8]. The search for novel snoRNA candidates was performed only on sequences that were not annotated as protein-coding or another ncRNA in the current S. mansoni assembly. The SnoReport program [73] was used to identify putative box C/Dand box H/ACA snoRNAs on both strands. Only the best predictions, i.e., those that show highly conserved boxes and canonical structural motifs, were kept for further analysis. The remaining candidates are further analysed for possible target interactions with ribosomal RNAs using snoscan [74] for box C/D and RNAsnoop [75] for box H/ACA snoRNA canidates. In addition, the sequences were checked for conservation in S. japonicum and S. mediterranea using NCBIblast. To estimate the number of false predictions we compared the candidate snoR-NAs with common ncRNA databases, in particular Rfam [57] and noncode [58]. All sequences that match a non-snoRNA ncRNA were discarded.

Other RNA families

For other families, we employed the following five steps:

(a) Candidate sequences for ribosomal RNAs, spliceosomal RNAs, the spliced leader and the SRP RNA, we performed blast searches with $E < 10^{-3}$ using the known ncRNA genes from the NCBI and For the snRNA set, see [40]. Rfam databases. For 7SL RNA we used X04249, for 5S and 5.8S rRNAs we used the complete set of Rfam entries, for the SSU and LSU rRNAs, we used Z11976 and NR_003287, respectively. The spliced-leader SL RNAs were searched using SL-RNA entries from Rfam and the sequences reported in [23]. For more diverged genes such as minor snRNAs, RNase MRP, 7SK, and RNase P, we used GotohScan [8], an implementation of a full dynamic programming alignment with affine gap costs. In cases where no good candidates where found we also employed descriptorbased search tools such as **rnabob** [http://selab.janelia.org/software.html].

(b) In a second step, known and predicted sequences were aligned using ClustalW [68] and visualized with ClustalX [76]. To identify functional secondary structure, RNAfold, RNAalifold, and RNAcofold [77] were used. Combined primary and secondary structures were visualized using stockholm-format alignment files in the emacs editor utilizing ralee mode [78]. Alignments are provided in the Supplemental Material.

(c) Putatively functional sequences were distinguished from likely pseudogenes by analysis of flanking genomic sequence. To this end, the flanking sequences of snRNA and SL RNA copies were extracted and analyzed for conserved sequence elements using meme [79]. Only snRNAs with plausible promoter regions were reported.

(d) Additional consistency checks were employed for individual RNA families, including phylogenetic analysis by neighbor-joining [80] to check that candidate sequences fall at phylogenetically reasonable positions relative to previously known homologs. For RNAse MRP RNA candidates, RNAduplex [http://www.tbi.univie.ac.at/ RNA/RNAduplex.html] was used to find the pseudoknot structure. In order to confirm that the SL RNA candidate is indeed transspliced to mRNA transcripts, we searched the FAPESP Genoma Schistosoma mansoni website http://bioinfo.iq.usp. br/schisto/ for ESTs including fragments of the predicted SL RNA. We found 52 ESTs with blast E < 0.001 that span the predicted region of the SL RNA (nt 8-38), indicating that this RNA does indeed function as a spliced leader.

(e) Accepted candidate sequences were used as **blast** queries against the *S. mansoni* genome to determine their copy number in the genome assembly.

Authors' contributions

CSC, PB, and PFS designed the study. CSC, MM, DR, JH, CBS, SK, CSA, and PFS performed the computational analyses. CSC wrote the first draft of the manuscript. All authors contributed to the final assessment of the data as well as the writing of the final version of the manuscript. CSC, MM, DR, JH should be considered as joint first authors.

Acknowledgements

This work was supported in part by the European Union through grants in the 6th and 7th framework programe of the European Union (projects EMBIO, SYNLET, and EDEN), the *Deutsche Forschungsgemeinschaft* und the auspices of SPP SPP-1174 "Deep Metazoan Phylogeny", the *Freistaat Sachsen*, and the DAAD-AleCol program.
